Abstract

The objective of this study was to describe the morphological, histological and histochemical structural features of the trachea of the camel (Camelus. dromedaries) Tracheas from 10 adult male camels aged between 3-5 years were collected from slaughter house in Al- samawa and Al- zubair distract. This study were performed at college of veterinary medicine / university of Basra. Clinically, all camels were appeared normal and healthy. The length, and the number of tracheal cartilage rings were measured and processed for histological study. The morphological study revealed that the mean length of the trachea was 95 ± 0.77 cm, while the mean number of the cartilage rings was 75.6 ± 0.74. The histological results revealed that the wall of trachea consist of mucosa, submucosa, hyaline cartilage and adventitia. The mucosa was lined by respiratory epithelium (pseudostratified ciliated columnar epithelium) with numerous goblet and basal cells, while the lamina propria was consisted of loose connective tissue. Muscularis mucosa was very thin layer, while the submucosa appeared as a layer of loose connective tissue and contained tubulo-acinar submucosal glands, which were very few in number and small in size. The hyaline cartilage layer was surrounded by perichondrium with the dense fibroblastic tissue presented between the cartilaginous rings. The adventitia was consisted of connective tissue with numerous elastic fibers. On the other hand the Periodic acid–Schiff stain (PAS) showed a positive reaction of goblet cells and submucosol gland.

Key word: One humped camel, Trachea, Histology, Periodic acid–Schiff stain

Introduction

Camels are in the taxonomic order Artiodactyls (even toed ungulates), sub order Tylopoda (pad-footed), Family camelids which has two species Camelus dromedarius (one humped) and Camelus bacterianus (two humped) (Klingel, 1990). The camel is considered as a very important animal, but it had received little attention when compared with other species of animals (Khattal et al., 2015). Respiratory system plays important role in olfaction, phonation and regulation of body temperature (Sellnow 2006; Baba and Choudhary, 2008).

The lower respiratory tract include the trachea, bronchi, bronchioles and the lungs. Trachea is a flexible tube composed of cartilaginous rings, connected by a fibromuscular membrane and lined internally by mucosa. It is composed of several of C-shaped tracheal cartilages in different species, which are open dorsally and the space is bridged by tracheal muscle (Dabanoglu and Kara, 2001). The structures of respiratory tract are varied among species and within each species (Legaspi, 2010). The trachea is composed of respiratory epithelium that surrounded by a submucosa and well-developed subtending adventitia with incomplete cartilaginous rings (Samuelson, 2013).

The purpose of this study was to describe the morphological, histological and histochemical structure of trachea of C. dromedarius using the routine and special histological stains.

Materials and Methods

Tracheas of ten adult male camels (C. dromedarius) were used for this study. The trachea of apparently normal and clinically healthy camels were collected from Al Samawa and Al Zubair abattoirs. These tracheas were dissected and flushed with normal saline. The trachea was dividing into three equal parts (proximal, middle and distal part) for morphological study. Lengths of the trachea were measured from the cranial border of the first tracheal ring to the tracheal bifurcation. In addition, the number of tracheal rings were also counted. By incising the tracheal annular ligaments, the transverse diameters, vertical diameters, and cartilage thickness were measured by using a ruler and digital caliper with an accuracy of ±0.02mm. (Tempest, 1980). For histological examination, the samples were fixed in 10% neutral buffered formalin for 72 h. Tissue samples were then dehydrated in a graded alcohol, cleared in xylol and embedded in paraffin wax. Each paraffin block was sectioned at (6μm) micrometers thickness and stained with haematoxylin and eosin, Masson’s trichrome and Van Giesson for collagen fibers, and periodic acid schiff stain (PAS) for histochemistry of muco-substances. (Luna,1968)

Result and Discussion

The results of this study showed that the trachea consisted of the installation of tubular shape made up of sequentially series of cartilaginous rings incomplete dorsally in the gross examination. The rings were connected with each other by
annular ligament and their ring edges were close by the tracheal muscle at their internal surface (Figure 1).

Trachea was lined with relatively thick mucous membrane. The length of trachea from the first to the last tracheal ring was 92-101 cm with a mean value of 95±0.77 cm. These results are disagree with previous study (Al-Zghoul et al., 2007). Al-Zghoul et al., (2007) reported the tracheal length (87±0.83 cm) in young Arabian camels with differences due to variation in the age. The number of the tracheal rings were varied from 72-79 with a mean value of 75.6±0.74. This result is compatible with similar values which was reported previously for the adult Indian camels (Kumar et al., 1992). However, this result is disagreed with (Cano and Perez, 2009), who described the trachea of giraffe and mentioned that it has (87-100) ring due to the length of the neck. The variation in numbers of tracheal rings between specimens was due to individual anatomical variations (Nickel et al., 1979). The diameters of tracheal rings was determined by calculation the mean diameter for three tracheal region. The means of proximal transverse, proximal vertical, middle transverse, middle vertical, distal transverse and distal vertical were 34.46±0.48 mm 41.98±0.32 mm, 29.85±0.25 mm 30.48±0.18 mm and 24.72±0.09 mm 26.68±0.24 mm respectively. The mean value of tracheal rings thickness for three part (proximal, middle and distal) are 6.55±0.03, 5.19±0.12, 3.92±0.07 mm respectively. The lumen of the trachea narrowing toward distal part with relatively degrees in thickness and bounded by bone such as first pair of ribs, vertebra (thoracic vertebra) and sternum which acts to facilitating movement of neck. Tracheal ring fusion with neighboring rings was observed within all different tracheal regions. Fusion of the tracheal rings occurred mostly in the cranial cervical region. It has been suggested that tracheal rings of this region are most affected by neck movements resulting in its fusion over time (Morgan et al., 1986). The shape of tracheal rings in the proximal part was semi-oval and the end of rings have relatively large opening laterally to appear as C-shape. In the middle part of trachea, the end of the rings was overlapping the left end on right end continuously with the distal part of the trachea, and each ring connected with next ring.

The histological examination from the proximal, middle and distal part of the trachea revealed that the wall of the trachea consist of mucosa, submucosa, hyaline cartilage and adventitia, (Figure 2). The luminal surface was completely covered by cilia,
which is similar to cattle, goat and neonatal kids (Abdel-Rahman, 1999). The mucosa was lined by pseudostratified ciliated columnar epithelium with numerous goblet and basal cells, goblet cells and basal cells. All these cells were rest on the basement membrane but not all of them reach the luminal surface, and their nuclei disposed at different levels (Figure. 3). These results are similar to those observed in most mammalian species (Ibe et al.,2011), in the sheep (Mariassy et al.,1983), in the goat (Kahwa and Purton,1996). The ciliated columnar cells were one of the most abundant cell types appeared as a tall columnar cells, with cilia covering their apical surfaces and extending into the tracheal lumen (Figure.2). Their cytoplasm was slightly stained with large oval shaped nuclei located near the epithelial surface (Figure.2). Similar features was observed in Yak (Yang et al., 2010). Goblet cells produce exclusive amounts of acidic and neutral mucosubstances (Figure.3).

In contrast, goblet cells in goat produce acidic mucosubstances, which is observed by Kahwa and Purton, (1996). The goblet cells showed appositive reaction toward PAS stain and revealed purple color due to mucopolysaccharide contents (Figure.4). Similar findng was observed by Raji and Naserpour, (2007). The mucous produced by goblet cell act as a protective barrier for the epithelium by lubricating, insulating and providing an appropriate condition for mucociliary clearance (Buchner and Maxwell, 1993). Lamina propria were loose connective tissue with prominent collagen and elastic fibers, blood vessels and lymphatic vessels (Figure.4). These features are similar to the histological features of cats and goats (William, 1990). The muscularis mucosa was very thin layer consist of few smooth muscle fibers (Figure.3) and such result comparable with the those found in cat Nasser(2012). The tunica submucosa appears as a layer of loose connective tissue contains different connective tissue cells, lymphocytes, monocytes, macrophage and plasma cells, blood vessels and the submucosal glands were very few in number,small in size and appeared as tubulo - acinar mucus type glands that were appositively reacted with PAS (Figure.4). The glands opened into the lumen of trachea by a slit shaped duct (Figure.4).
Similar features was also reported previously by Choi and Finkbeiner, (2000). The tracheal muscle was smooth and lied internal to the open end of the horseshoe-shaped hyaline cartilage as seen in other ruminants. It is noteworthy that tracheal muscle lies external to the cartilages in the carnivores (Nickel and Schumer, 1979). (Figure. 4). The hyaline cartilage layer was surrounded by perichondrium with the dense fibroblastic tissue present between the cartilaginous rings, it contain the chondrocytes inside the lacuna within an amorphous matrix (Figure.2).The adventitia was consisted of connective tissue with numerous elastic fibers that are similar to cat (William, 1990).
